A Global Optimization Technique for Statistical Classifier Design

David Miller, *Member, IEEE,* Ajit V. Rao, *Student Member, IEEE,* Kenneth Rose, *Member, IEEE,* and Allen Gersho, *Fellow, IEEE*

Abstract— **A global optimization method is introduced for the design of statistical classifiers that minimize the rate of misclassification. We first derive the theoretical basis for the method, on which we base the development of a novel design algorithm and demonstrate its effectiveness and superior performance in the design of practical classifiers for some of the most popular structures currently in use. The method, grounded in ideas from statistical physics and information theory, extends the deterministic annealing approach for optimization, both to incorporate structural constraints on data assignments to classes and to minimize the probability of error as the cost objective. During the design, data are assigned to classes *in probability* so as to minimize the expected classification error given a specified level of randomness, as measured by Shannon's entropy. The constrained optimization is equivalent to a free-energy minimization, motivating a deterministic annealing approach in which the entropy and expected misclassification cost are reduced with the temperature while enforcing the classifier's structure. In the limit, a hard classifier is obtained. This approach is applicable to a variety of classifier structures, including the widely used prototype-based, radial basis function, and multilayer perceptron classifiers. The method is compared with learning vector quantization, back propagation (BP), several radial basis function design techniques, as well as with paradigms for more directly optimizing all these structures to minimize probability of error. The annealing method achieves significant performance gains over other design methods on a number of benchmark examples from the literature, while often retaining design complexity comparable with or only moderately greater than that of strict descent methods. Substantial gains, both inside and outside the training set, are achieved for complicated examples involving high-dimensional data and large class overlap.**

I. Introduction

THE problem of designing a statistical classifier to minimize the probability of misclassification or a more general risk measure has been a topic of continuing interest since the 1950's. Much of the early, classical work focused on linear classifiers [40], [14], [46] and parametric classifiers, e.g., [9]. More recently, with the increase in power of serial and parallel computing resources, a number of more complex classifier structures have been proposed, along with associated learning algorithms to design them. The most prominent research has focused on several structures: decision trees [3], [32] and extensions thereof [5], [12]; nearest-prototype (NP) classifiers with the learning vector quantizer (LVQ) design [21]; radial basis function (RBF) classifiers [29]; and multilayer perceptrons (MLP's) [42]. Several review articles discuss the tradeoffs in performance, memory, implementation complexity, and design complexity for the various classification schemes as well as recent developments relating to these approaches [24], [16]. Much attention has focused on MLP's, primarily due to the increasing interest in neural network models and in their applicability for a variety of signal processing applications. MLP's and other neural network models have been investigated as alternatives to more traditional classifiers for engineering applications such as speech recognition [23], [13], [1] as well as in the contexts of statistical and scientific inquiry [35]. MLP's can form complex decision boundaries [25], with the associated classification rule efficiently implementable via parallel processing. While neural networks offer powerful structures for classification, their potential cannot be fully realized without effective learning procedures well-matched to the minimum classification-error objective.

A. Limitations of Conventional Methods

The standard back propagation (BP) learning algorithm for MLP's [42] uses as its design objective the minimization of the distance between the continuous network output and a target output associated with the discrete class label (which is binary for the two-class case). Essentially, this approach views the learning problem for classification as the design of a *regression* model to fit to the class targets. Recently, several researchers have recognized that this objective is not equivalent to minimizing the probability of misclassification. Rather, BP learning for MLP's, as well as corresponding techniques for other classifiers, effectively train the networks to approximate the Bayes-optimal discriminant function or, equivalently, to estimate the *a posteriori* probabilities that data belong to a given class [34], [41], [52], [9]. While large networks can in principle provide a close fit to the Bayes discriminant function, in practice, the network size must be constrained to avoid high complexity and the problem of overfitting the network to the (finite-length) training set. Thus, networks trained by BP or related learning algorithms might

achieve substantially poorer classification performance than networks trained by alternative methods.

A number of researchers have proposed modified cost objectives and/or learning algorithms that better match the goal of minimizing classification error (or minimizing risk, if errors are not weighed equally) [8], [21], [13], [47], [19], [49], [31]. Many of these methods implement descent techniques such as gradient descent or related approaches, either of a sequential or batch nature, on a cost surface that is a "smoothed" approximation to the misclassification error cost surface. "Smoothing" the classification cost is necessary because it is a piecewise constant surface whose zero gradients are useless for a descent procedure [8], [19], [31]. This basic design approach has been described as discriminative learning [19]. Discriminative learning techniques have a potential advantage over regression-based approaches for classification (e.g., BP) in the following important sense: The regression approach weights all errors in the estimates of *a posteriori* probabilities *equally*, whereas implementation of the Bayes decision rule really only requires accurate estimation of the *largest* class *a posteriori* probabilities. Thus, in the regression approach, parameters of the model are effectively required to learn "more" than what is necessary to achieve accurate classification, which may limit the performance achievable given a fixed model size. By contrast, discriminative learning essentially trains the model parameters solely to move the resulting classifier decision boundaries to directly reduce the error rate.

While this general paradigm optimizes MLP's and other classifiers to effectively minimize classification error, a serious concern is the potential to fall into poor local minimum traps, which often riddle the energy surface. Several researchers have noted problems of local optima in neural networks [47], [49], [53], [35], as well as related difficulties in optimizing the full complement of model parameters (see [48] for a study on RBF's). Moreover, some studies have also reported on the complex nature of the energy surface, which can cause slow convergence of descent techniques [15]. Nevertheless, much of the work in the literature appears to ignore these problems, and there have been few practical approaches addressing them. Typically, efforts to avoid poor local optima of the cost have been limited to the practice of generating numerous solutions based on random initialization and then choosing the best result [35]. Since it is not well understood how the number and quality of local optima may depend on the data distributions, the network model, and its size, there are no guarantees that this "sampling" approach to classifier design will yield good solutions. Moreover, while stochastic optimization approaches such as simulated annealing (SA) [20] can be applied at least in principle, the computational complexity of such methods is often prohibitive.

B. Structurally Constrained Deterministic Annealing for Classifier Design

As an alternative to strict descent-based procedures, we propose a new deterministic learning algorithm for statistical classifier design with a demonstrated potential for avoiding local optima of the cost. Several deterministic annealing-based techniques have been proposed for avoiding nonglobal optima in computer vision and image processing [54], [10], [2], in combinatorial optimization [51], [45], and elsewhere. Our approach is derived based on ideas from information theory and statistical physics and builds on the probabilistic framework of the deterministic annealing (DA) approach to clustering and related problems [37]–[39]. In the DA approach for data clustering, the maximum entropy principle [17] was invoked to obtain the distributions at a given level of expected cost. In recent work [26], [27], we have extended this formulation to attack a larger class of optimization problems than was originally conceived. The new formulation emphasizes the quantity in statistical physics known as the Helmholtz free energy [4] as the effective cost function. This formulation explicitly characterizes the deterministic annealing process as a gradual reduction in both the entropy and cost of the system with decreasing "temperature," where the temperature parameter is a Lagrange multiplier controlling the system's cost and entropy. While equivalent to other formulations of deterministic annealing, the approach based on the Helmholtz free energy is found to be especially useful in extending DA-based optimization techniques to incorporate *structural constraints* on data assignments.

It is noted that prior work on deterministic annealing, e.g., [38], [54], [44], [10], [2], [51] addressed data association problems of a combinatorial nature such as data clustering, graph partitioning, and matching problems for which the cost can be expressed explicitly through binary (0-1) assignment variables. In these problems, the "data" of the problem is freely assigned to "classes" or "groups" via the binary assignment variables. The novel contribution of this work relative to prior work on deterministic annealing is its extension of the annealing framework to incorporate structural constraints on the assignments of data to classes. By *structurally constrained* data assignments, it is meant that the data assignments are constrained to agree with a parameterized classification rule, such as that of a nearest prototype classifier, a decision tree, or a neural network model. Examples of structurally constrained data association problems include fundamental statistical learning problems such as statistical classification, piecewise regression, and structured (e.g., tree-structured) vector quantization.

Appropriately, the extension of DA methods to incorporate structure is best seen within the learning context. We note that recent work has related techniques from statistical physics to the learning problem via a connection with likelihood estimation [36], [55], [28]. In [55], it was noted that the binary assignment variables in the combinatorial optimization problem can be related to the unknown or "hidden" data in methods for maximum likelihood estimation such as the expectation/maximization (EM) algorithm [7]. From this point of view, the cost associated with the combinatorial optimization problem is interpreted as the complete data likelihood of a corresponding estimation problem. Similar observations were made for problems specifically involving images, e.g., [56]. This connection between statistical physics and statistical estimation suggested that deterministic annealing could be

applied to the learning problem when the learning objective is maximum likelihood estimation (MLE) [55], [28]. MLE techniques have long been applied to unsupervised learning [9], and supervised learning problems such as regression have also recently been posed as likelihood estimation [18]. However, while likelihood estimation is an important learning objective, maximizing the model's likelihood is not equivalent to optimizing parameters of a classifier to directly minimize probability of error if the goal is classification nor to choosing model parameters to directly minimize mean-squared error if the goal is regression. These are often the desired supervised learning objectives. In the classification context, we have already pointed out the potential advantage of directly minimizing probability of error, which has been exploited by discriminative learning techniques. Previous physics-based approaches do not anneal over models to directly minimize desired supervised learning objectives such as probability of error, but as will be seen in the sequel, the formulation suggested here based on the Helmholtz free energy incorporates both the model's structure and its cost directly within the optimization framework and anneals over the structure to directly minimize the supervised learning objective. In this work, we develop a structurally constrained extension of DA, specialized for the problem of designing statistical classifiers to minimize probability of error. In addition to its relation to prior work on deterministic annealing, we will also point out the connection between our method and discriminative learning techniques.

Whereas most design methods have been developed for specific classifier structures, e.g. [21], [29], [42] (an exception is the approach in [19]), the method we develop can be applied generally to optimize a variety of structures. In this work, we will develop algorithms and demonstrate results for three of the most widely used structures: nearest-prototype classifiers, radial basis function classifiers, and multilayer perceptrons. Our method will be demonstrated to provide substantial performance gains over conventional design techniques for all of these structures while retaining design complexity in many cases comparable to the strict descent methods. Our approach often designs small networks to achieve training set performance that can only be obtained by a much larger network designed in a conventional way. The design of smaller networks may translate to more robust solutions and superior performance outside the training set as we will note in particular for MLP and RBF networks. We thus provide a general approach for designing statistical classifiers based on training data that avoids many local minima that trap other known methods and achieves classifier designs superior to those obtained by other methods.

C. Outline of This Paper

In the next section, we first state the problem, introduce mathematical notation, and briefly review the commonly used NP, RBF, and MLP classifier structures. We then develop our probabilistic framework for optimization, which leads to a general classifier design method. The formulation is next specialized for the different structures, yielding separate DA learning algorithms for each structure. In Section III, we provide performance comparisons between classifiers designed by the DA approaches and by conventional techniques, drawing on several sources of benchmark data from the literature. We then conclude with some discussion and suggestions for future work.

II. Classifier Design Formulation

A. Problem Statement

Let $\mathcal{T} = \{(\mathbf{x}, c)\}$ be a training set of N labeled vectors, where $\mathbf{x} \in \mathcal{R}^n$ is a feature vector, and $c \in \mathcal{I}$ is its class label from an index set $\mathcal{I}$. A classifier is a mapping $C : \mathcal{R}^n \rightarrow \mathcal{I}$, which assigns a class label in $\mathcal{I}$ to each vector in $\mathcal{R}^n$. Typically, the classifier is represented by a set of model parameters $\Lambda = \{\Lambda_k\}$. The classifier specifies a partitioning of the feature space into regions $R_j \equiv \{\mathbf{x} \in \mathcal{R}^n : C(\mathbf{x}) = j\}$, where $\bigcup_j R_j \equiv \mathcal{R}^n$ and $\bigcap_j R_j \equiv \emptyset$. It also induces a corresponding partitioning of the training set into subsets $\mathcal{T}_j \equiv \{(\mathbf{x}, c) \in \mathcal{T} : C(\mathbf{x}) = j\}$. A training pair $(\mathbf{x}, c) \in \mathcal{T}$ is *misclassified* if $C(\mathbf{x}) \neq c$. The performance measure of primary interest is the empirical error fraction P_e of the classifier, i.e., the fraction of the training set (for generalization purposes, the fraction of the test set), which is misclassified

$$P_e = \frac{1}{N} \sum_{(\mathbf{x},c)\in\mathcal{T}} \rho(c, C(\mathbf{x})) = \frac{1}{N} \sum_{j\in\mathcal{I}} \sum_{(\mathbf{x},c)\in\mathcal{T}_j} \rho(c, j) \quad (1)$$

where $\rho(c, j) = 1$ if $c \neq j$ and 0 otherwise. Our goal is to optimize statistical classifiers for this performance measure. Although the approach we will develop addresses a variety of structures, for concreteness, we will focus on three of the most commonly used classifiers: the NP, RBF, and MLP classifiers. We now briefly review these network models and their associated classification rules.

1) Nearest-Prototype (NP) Classification: The NP classifier structure is shown in Fig. 1. The classifier is specified by the parameter set $\Lambda = \{\mathbf{x}_{jk}\}$, where $\mathbf{x}_{jk} \in \mathcal{R}^n$ is the kth prototype associated with class $j \in \mathcal{I}$. The NP classifier maps a vector in $\mathcal{R}^n$ to the class associated with the nearest prototype, specifying a partition of $\mathcal{R}^n$ into the regions

$$R_j \equiv \bigcup_k S_{jk} \text{ with}$$
$$S_{jk} \equiv \{\mathbf{x} \in \mathcal{R}^n : d(\mathbf{x}, \mathbf{x}_{jk}) \leq d(\mathbf{x}, \mathbf{x}_{lm}) \forall l, m\} \quad (2)$$

i.e., each region R_j is the union of Voronoi cells S_{jk}. Here, $d(\cdot, \cdot)$ is the "distance measure" used for classification. For consistency with the neural network models to follow, which classify based on the *largest* output of the network ("winner takes all"), we note trivially that the classification rule can also be written as

$$R_j \equiv \bigcup_k S_{jk} \text{ with}$$
$$S_{jk} \equiv \{\mathbf{x} \in \mathcal{R}^n : F_{jk}(\mathbf{x}) \geq F_{lm}(\mathbf{x}) \forall l, m\} \quad (3)$$

by choosing $F_{jk}(\mathbf{x}) \equiv -d(\mathbf{x}, \mathbf{x}_{jk})$.

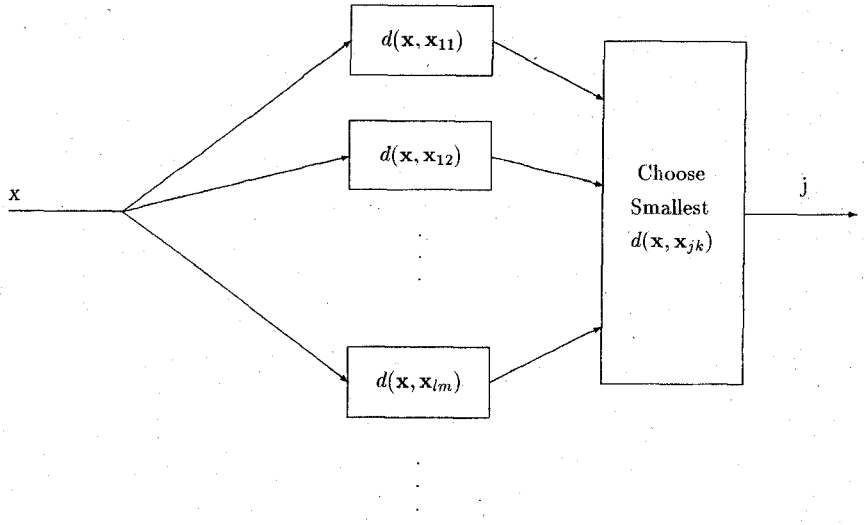

Fig. 1. Prototype-based architecture for classification.

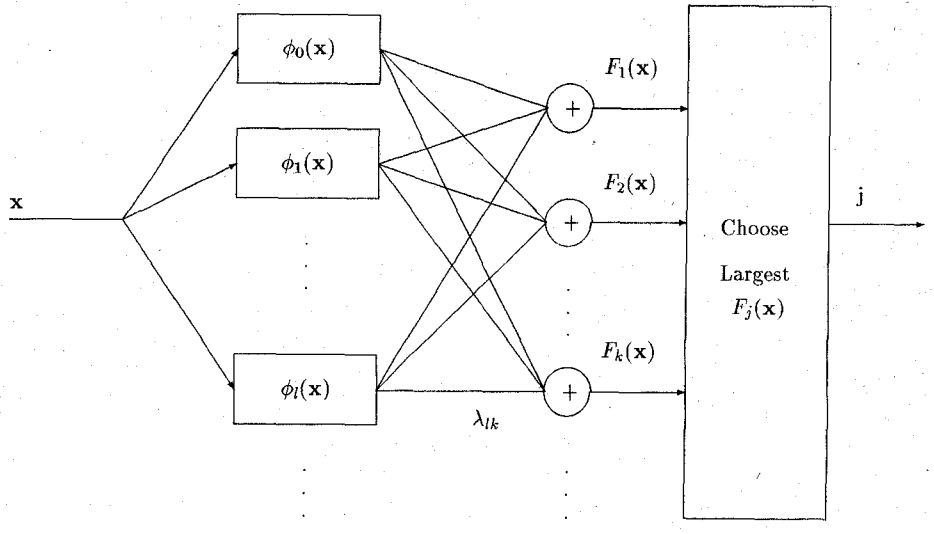

Fig. 2. RBF architecture for classification.

One weakness of prototype-based classification is the need to specify the allocation of model parameters (the prototypes) to the respective classes. Typically, this allocation is heuristic, leading to a suboptimal distribution of parameters, with some classes deficient and others maintaining a surplus of prototypes. The RBF and MLP models we next examine eliminate this problem, as all parameters (excepting weights to the output layer) contribute to each class output.

2) Radial Basis Function (RBF) Classification: The RBF classifier structure is shown in Fig. 2. The classifier is specified by a set of Gaussian receptive field functions $\{e^{-\frac{|\mathbf{x}-\mu_k|^2}{\sigma_k{}^2}}\}$ and by a set of scalar weights $\{\lambda_{kj}\}$ that connect each of the receptive fields to the class outputs of the network. Thus, $\Lambda = \{\{\mu_k\}, \{\sigma_k{}^2\}, \{\lambda_{kj}\}\}$. The parameter μ_k is the "center" vector for the receptive field, and $\sigma_k{}^2$ is its "width." In the "normalized" representation for RBF's [29], which we will adopt here, the network output for each class is written in the form

$$F_j(\mathbf{x}) = \sum_k \lambda_{kj}\phi_k(\mathbf{x}) \tag{4}$$

where

$$\phi_k(\mathbf{x}) = \frac{e^{-\frac{|\mathbf{x}-\mu_k|^2}{\sigma_k{}^2}}}{\sum_l e^{-\frac{|\mathbf{x}-\mu_l|^2}{\sigma_l{}^2}}}. \tag{5}$$

Since $\phi_k(\cdot)$ can be viewed as a probability mass function, each network output is effectively an average of weights emanating from each of the receptive fields. The classifier maps the vector $\mathbf{x}$ to the class with the largest output

$$R_j \equiv \{\mathbf{x} \in \mathcal{R}^n : F_j(\mathbf{x}) \geq F_k(\mathbf{x}) \forall k \in \mathcal{I}\}. \tag{6}$$

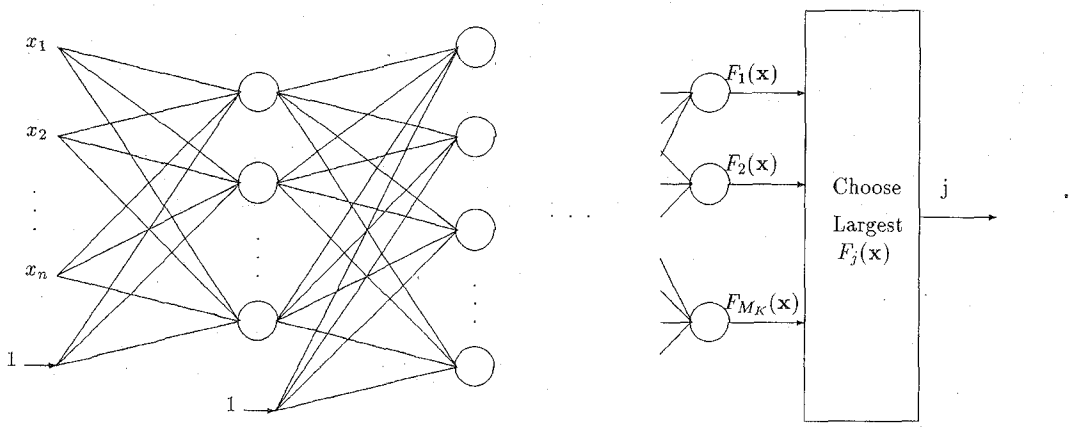

Fig. 3. MLP architecture for classification.

3) Multilayer Perceptron (MLP) Classification: The MLP classifier structure is shown in Fig. 3. We restrict ourselves to the MLP structure with a binary output unit per class.[1] The classification rule for MLP's is the same as that for RBF's (6), but the output functions $\{F_j(\cdot)\}$ are parametrized differently.

The input $\mathbf{x}$ passes through K layers with M_k neurons in layer k. We define u_{kj} to be the output of hidden unit j in layer k, with the convention that layer 0 is the input layer $u_{0j} = x_j$ and layer K is the output layer $u_{Kj} = F_j(\mathbf{x})$. To avoid special notation for thresholds, we define the augmented output vector of layer k as $\tilde{\mathbf{u}}_k = [u_{k1}u_{k2}\ldots u_{kM_k}1]^T$. This is a standard notation allowing us to replace thresholds by synaptic weights that multiply a fixed input value of unity. The weight matrix $\mathbf{W}_k$ connects the augmented outputs of layer $k-1$ and the neurons of layer k. The activation function of the kth layer is the vector valued function $\mathbf{f}_k : \mathcal{R}^{M_k} \rightarrow \mathcal{R}^{M_k+1}$defined as $\mathbf{f}_k(\mathbf{v}) = [f_k(v_1)f_k(v_2)...f_k(v_{M_k})1]^T$, where $f_k(\cdot)$ is the scalar activation function used by all neurons in the kth layer. In our experiments, we used the logistic activation function $(f_k(v) = \frac{1}{1+e^{-v}})$ for the hidden layers $k = 1,\ldots,K-1$, and the linear activation function $(f_K(v) = v)$ for the output layer. The *activity level* at the input of the kth layer is given by

$$\mathbf{v}_k = \mathbf{W}_k\tilde{\mathbf{u}}_{k-1}. \tag{7}$$

Thus, the network's operation can be described by the following recursion formula:

$$\tilde{\mathbf{u}}_k = \mathbf{f}_k(\mathbf{v}_k) = \mathbf{f}_k(\mathbf{W}_k\tilde{\mathbf{u}}_{k-1})\ k = 1,2,\ldots,K. \tag{8}$$

B. Approach to Classifier Design

Although we have described three distinct classifier structures, the operation of each is consistent with that of a general network model: Given a feature $\mathbf{x}$, the network produces competing class outputs $\{F_j(\mathbf{x})\}$, and then, classification decisions are made based on the largest, "winning" output. Note that this model is identical to the standard (or canonical) representation of classifiers via maximization over a set of *discriminant functions* [9], where the discriminant functions are given here by $F_j(\mathbf{x})$. Any (hard) classifier can be represented by this model, albeit possibly with complicated discriminant functions. We now use this convenient representation to develop a general optimization approach for statistical classifier design.

1) Maximum Entropy and Equivalent Principles: Our probabilistic design approach can be motivated by several different points of view, which are practically equivalent (since they lead to the same optimization method) but which are philosophically distinct. One perspective is that of the maximum entropy principle. According to [17], the least biased distribution is that which maximizes entropy subject to constraints which incorporate what is known about a system. Often, the constraints are expectation constraints, specifying quantities such as "energy," using the physical analogy. In the context of the optimization problem, constraints on entropy maximization can be used to introduce the expected cost. The maximum entropy principle was used to develop a DA method for clustering [37] and related optimization problems [38], [39]. However, this principle is not universally accepted.[2] An equivalent, alternative approach that may at least have more intuitive appeal for optimization is to find the distribution that minimizes the expected cost given a constrained level of randomness in the solution. A natural, information-theoretic measure of randomness or uncertainty is the Shannon entropy. Thus, we can state the problem of finding the *best* distribution in the sense of minimum expected cost given a constrained level of entropy. The equivalence between these two methods—i) maximizing entropy given a constraint on expected cost and ii) minimizing expected cost given constrained entropy—is easily seen through the (unconstrained) Lagrangian cost objective, which both approaches share. In the derivation that follows, the minimum expected cost formulation is chosen. Both methods can be connected with statistical physics by noting that the Lagrangian cost objective can be interpreted as the Helmholtz free energy [4] of a simulated system. From this perspective, the expected cost is the "energy" of the system and the Lagrange multiplier is the "temperature." This connection with statistical physics will be made more concrete in the sequel.

[1] Note that other architectures for classification are also possible, e.g., MLP or RBF architectures with a binary output code, wherein the number of output units is logarithmically related to the number of classes. For this classifier model, individual binary classification decisions are made for each output unit, and the resulting bits specify the class.

[2] The maximum entropy principle was given an axiomatic basis in [43] and was shown to be a consequence of conditional probability theory in [50] and [6].

2) Randomized Classifier Partition: Whereas statistical classifiers that minimize probability of error almost invariably implement a deterministic function, producing "hard" classification decisions[3], it may still be useful in the context of the classifier *design* to allow points to be assigned to classes *in probability*. As in the original DA approach for data clustering [37], we cast the optimization problem in such a probabilistic framework, considering a "random" classifier characterized by a probabilistic assignment of data to classes. Accordingly, we define the *probabilities of association* between a feature $\mathbf{x}$ and the class regions, i.e.,$\{P[\mathbf{x} \in R_j]\}$. As our design method, which optimizes over these probabilities, must ultimately form a classifier that makes "hard" decisions based on a specified network model, the distributions must be chosen to be consistent with the decision rule of the model. In other words, we need to introduce randomness into the classifier's partition. Clearly, there are many ways one could define probability distributions that are consistent with the hard partition at some limit. We use an information-theoretic approach. We measure the randomness or uncertainty by the *Shannon entropy* and determine the distribution for a given level of entropy. At the limit of zero entropy, we should recover a hard partition. For now, suppose that the values of the model parameters $\Lambda = \{\Lambda_k\}$ have been fixed. We can then write an objective function whose maximization determines the hard partition for a given Λ:

$$F_h = \frac{1}{N} \sum_{j \in \mathcal{I}} \sum_{(\mathbf{x},c) \in \mathcal{I}_j} F_j(\mathbf{x}). \tag{9}$$

Note that the winner-take-all rule (6) is optimal in the sense of F_h. Specifically, maximizing (9) over all possible partitions captures the decision rule of (6). The probabilistic generalization of (9) is

$$F = \frac{1}{N} \sum_{(\mathbf{x},c) \in \mathcal{T}} \sum_{j} P[\mathbf{x} \in R_j] F_j(\mathbf{x}) \tag{10}$$

where the partition is now represented by association probabilities, and the corresponding entropy is

$$H = -\frac{1}{N} \sum_{(\mathbf{x},c) \in \mathcal{T}} \sum_{j} P[\mathbf{x} \in R_j] \log P[\mathbf{x} \in R_j]. \tag{11}$$

It is emphasized that H measures the average level of uncertainty *in the classification decisions*. We determine our assignment distribution at a given level of randomness as the one that maximizes F while maintaining H at the prescribed level $\hat{H}$:

$$\max_{\{P[\mathbf{x} \in R_j]\}} F \text{ subject to } H = \hat{H}. \tag{12}$$

The result is the *best* probabilistic partition in the sense of the structural objective F *at the specified level of randomness*. For $\hat{H} = 0$, we get back the hard partition, maximizing (9) and thus satisfying the winner-take-all classifier structure. At any $\hat{H}$, the solution of (12) is the Gibbs distribution

$$P[\mathbf{x} \in R_j] = \frac{e^{\gamma F_j(\mathbf{x})}}{\sum_k e^{\gamma F_k(\mathbf{x})}} \equiv P_{j|x}(\Lambda) \tag{13}$$

where γ is the Lagrange multiplier controlling the level of entropy. For $\gamma \to 0$, the associations become increasingly uniform, whereas for $\gamma \to \infty$, they revert to hard classifications, which are equivalent to application of the rule in (6). Thus, (13) is a probabilistic generalization of the winner-take-all classifier that satisfies its structural constraint, which is specified by (6), for the choice $\gamma \to \infty$. Note that the probabilities depend on Λ through the network outputs. Here, we have emphasized this dependence through our choice of concise notation. Equation (13) applies as is for MLP's and RBF's. However, for prototype-based classification, we randomize over the subregions S_{jk}, leading to

$$P[\mathbf{x} \in S_{jk}] \equiv P_{jk|x}(\Lambda) = \frac{e^{\gamma F_{jk}(\mathbf{x})}}{\sum_l \sum_m e^{\gamma F_{lm}(\mathbf{x})}} \tag{14}$$

and since $R_j = \bigcup_k S_{jk}$, we have

$$P_{j|x}(\Lambda) = \sum_k P_{jk|x}(\Lambda). \tag{15}$$

This distribution reduces to the decision rule of (3) for $\gamma \to \infty$. In the next section, we will describe an optimization technique that gradually introduces the objective of maximizing F, ultimately yielding a hard classifier that maximizes F_h and thus achieves the winner-take-all structure.

3) Design by Deterministic Annealing: Until now, we formulated a controlled way of introducing randomness into the classifier's partition while enforcing its structural constraint. However, the derivation assumed that the model parameters were given, and thus produced only the *form* of the distribution $P_{j|x}(\Lambda)$, without actually prescribing how to choose the values of its parameter set. Moreover, the derivation did not consider the ultimate goal of minimizing the probability of error. Here, we remedy both shortcomings.

The method we suggest gradually enforces formation of a hard classifier minimizing the probability of error. We start with a highly random classifier and a high expected misclassification cost. We then gradually reduce both the randomness and the cost in a deterministic learning process that enforces formation of a hard classifier with the requisite structure. While the motivation behind this basic approach remains as yet unclear, in the sequel, we will relate this process to annealing methods from statistical physics and show the method to be useful for avoiding poor local optima of the cost. As before, we need to introduce randomness into the partition while enforcing the classifier's structure. Now, however, we are also interested in minimizing the expected misclassification cost. While satisfying these multiple objectives may appear to be a formidable task, the problem is greatly simplified by restricting the choice of random classifiers to the set of distributions $\{P_{j|x}(\Lambda)\}$ as given in (13) or (15). These random classifiers naturally enforce the

[3]We note that fuzzy or multivalued decisions may sometimes be useful when there is uncertainty in the class labels or when the data is not well-represented by "crisp" categories or classes [22]. Otherwise, however, classifier systems designed to minimize probability of error may introduce fuzziness at intermediate stages of the data processing but ultimately make hard decisions.

structural constraint of (3) or (6) through γ, as we explained earlier. Thus, from the parametrized set $\{P_{j|x}(\Lambda)\}$, we seek that distribution that minimizes the average misclassification cost while constraining the entropy

$$\min_{\gamma,\Lambda} < P_e > \equiv \min_{\gamma,\Lambda} \frac{1}{N} \sum_{(\mathbf{x},c)\in\mathcal{T}} \sum_{j} P_{j|x}(\Lambda)\rho(c,j) \qquad (16)$$

subject to

$$H = \hat{H}.$$

The distribution is chosen by optimization over its parameter set. The solution yields the best random classifier in the sense of minimum $< P_e >$ for given $\hat{H}$. At the limit of zero entropy, we should get the best *hard* classifier in the sense of P_e with the desired structure, which is specified by (3) or (6).

The constrained minimization (16) is equivalent to the unconstrained minimization of the Lagrangian

$$\min_{\Lambda,\gamma} L \equiv \min_{\Lambda,\gamma} \beta < P_e > -H \qquad (17)$$

where β is a Lagrange multiplier controlling the tradeoff between H and $< P_e >$. For $\beta = 0$, the sole objective is entropy maximization, which is achieved by the uniform distribution. This solution, which is the global minimum for L at $\beta = 0$, can be obtained by choosing $\gamma = 0$. At the other extreme, for $\beta \to \infty$, the sole objective is to minimize $< P_e >$ and is achieved by choosing a nonrandom (hard) classifier (hence minimizing P_e). The hard solution satisfies the classification rule ((3) or (6)) and is obtained for $\gamma \to \infty$.

Motivation for minimizing the Lagrangian can be obtained from a physical perspective by noting that L is the Helmholtz free energy of a simulated system, with

$< P_e >$	"the energy of the system"
H	its entropy
$\frac{1}{\beta}$	the "temperature."

Thus, from this physical view, we can suggest a *deterministic annealing* (DA) process, which involves minimizing L starting at the global minimum for $\beta = 0$ (high temperature) and tracking the solution while increasing β toward infinity (zero temperature). In this way, we obtain a sequence of solutions of decreasing entropy and expected misclassification cost. Each such solution is the best random classifier in the sense of $< P_e >$ for a given level of randomness. The annealing process is useful for avoiding local optima of the cost $< P_e >$ and minimizes $< P_e >$ directly at low temperature. The approach we suggest is an extension of previous DA methods, which considers the probability of error as the cost objective. However, the approach that we suggest also extends DA-based methods in a more fundamental way as well, as it allows annealing to occur *in the structural objective*, as well as in the system's expected cost and entropy. To clarify this statement, we observe that while the annealing process suggested here ostensibly involves the quantities H and $< P_e >$, the restriction to $\{P_{j|x}(\Lambda)\}$ from (13) ensures that the process also enforces the structural constraint on the classifier in a controlled way, through the objective F. *Note, in particular, that γ has not lost its interpretation as a Lagrange multiplier determining F.* Thus, $\gamma = 0$ means that F is unconstrained; we are free to choose the uniform distribution. Similarly, sending $\gamma \to \infty$ requires maximizing F (see (12) and (13)), hence, the hard solution, which maximizes F_h and satisfies (6). Since γ is chosen to minimize L, this parameter effectively determines the level of F—which is the level of structural constraint—which is consistent with H and $< P_e >$ for a given β. As β is increased, the entropy constraint is relaxed, allowing greater satisfaction of *both* the minimum $< P_e >$ and maximum F objectives. At the limit of $\beta \to \infty$, γ is also driven to infinity; therefore, a hard classifier results, maximizing F_h and, hence, achieving the winner-take-all structure, as well as directly minimizing the probability of error objective. Thus, annealing in β gradually enforces both the structural objective F (via γ) and the minimum $< P_e >$ objective.[4]

The physical interpretation of the Lagrangian makes the connection with stochastic annealing methods clear: Rather than generating a stochastic solution process, which spends a long time at each temperature in order to reach thermal equilibrium, the DA approach performs a direct, deterministic optimization of the quantity that is stochastically optimized by SA at equilibrium—the free energy.[5] In addition to the connection with SA, our formulation also clearly identifies the relationship between the DA and discriminative learning (DL) methods. Note that the DA method performs a randomization at a given temperature, which achieves cost smoothing in much the same way as discriminative learning techniques. Thus, DL can be interpreted from the perspective of our DA framework as essentially minimizing the smoothed cost $< P_e >$ directly over the classifier parameters without controlling the entropy of the data assignments along the way. DL must choose the initial classifier parameters and the initial amount of cost smoothness. These choices may have significant bearing on the achieved solution quality. By contrast, the DA approach controls the level of cost smoothness (now characterized by the entropy of the random classifier) as well as F and $< P_e >$. These quantities are gradually varied through incremental temperature reduction, starting from a high entropy state, with the ultimate objective a global minimum energy configuration (error count) and a desired classifier structure at low temperature. As we will experimentally verify through simulations, our annealing approach outperforms design based on directly minimizing $< P_e >$.

C. Necessary Optimality Conditions

Minimization of the Lagrangian at a given β can be realized by gradient descent or any other local function minimization technique. Here, we derive necessary optimality conditions, presenting them in a convenient form to aid interpretation. For concreteness, in this section, we will assume a model

[4] Note, too, that while our method varies β and optimizes γ, an alternative annealing approach that will not be discussed here could possibly involve varying γ, i.e., introducing an increasing constraint on the classifier's structure, and optimizing a parameter that determines the tradeoff between $< P_e >$ and H. The feasibility of such an approach will not be investigated in this paper.

[5] However, whereas SA has been shown to converge in distribution to a uniform distribution over the set of globally optimal solutions, no similar proof exists for DA.

consistent with the RBF and MLP classifiers. We first rewrite the Lagrangian of (17) explicitly as

$$L = \frac{1}{N} \sum_{(\mathbf{x},c)\in\mathcal{T}} \sum_j P_{j|x}(\Lambda)\{\beta\rho(c,j) + \log P_{j|x}(\Lambda)\} \quad (18)$$

$$\equiv \frac{1}{N} \sum_{(\mathbf{x},c)\in\mathcal{T}} \left\{ \sum_j P_{j|x}(\Lambda) L_{xj} \right\} \equiv \frac{1}{N} \sum_{(\mathbf{x},c)\in\mathcal{T}} L_x. \quad (19)$$

The braces in (18) identify L_{xj}, which is the contribution to the cost when the feature $\mathbf{x}$ is assigned to class j, and the braces in (19) identify $L_x \equiv < L_{xj} >_j$, which is the average contribution for this feature.[6] Noting that the contributions to the derivative of L are additive over the data and applying the chain rule, we may write

$$\frac{\partial L_x}{\partial \Lambda_k} = \sum_j \frac{\partial L_x}{\partial P_{j|x}(\Lambda)} \frac{\partial P_{j|x}(\Lambda)}{\partial \Lambda_k} \quad (20)$$

and

$$\frac{\partial L}{\partial \Lambda_k} = \frac{1}{N} \sum_x \frac{\partial L_x}{\partial \Lambda_k}. \quad (21)$$

Setting $\frac{\partial L}{\partial \Lambda_k} = 0$ and simplifying, we obtain the necessary optimality condition

$$\sum_x \sum_j L_{xj} P_{j|x} \left(\frac{\partial F_j(\mathbf{x})}{\partial \Lambda_k} - < \frac{\partial F_l(\mathbf{x})}{\partial \Lambda_k} >_l \right) = 0, \forall k. \quad (22)$$

(Note that in (22), we have dropped explicit representation of the distribution's dependence on Λ for convenience.) In a similar fashion, the condition $\frac{\partial L}{\partial \gamma} = 0$ yields

$$\sum_x \sum_j L_{xj} P_{j|x} (F_j(\mathbf{x}) - < F_l(\mathbf{x}) >_l) = 0. \quad (23)$$

We have obtained the mathematical conditions for optimality. In what follows, we give some intuitive interpretation. In particular, conditions (22) and (23) can be viewed, appropriately, within the context of supervised learning. Toward this end, note that L can be interpreted as a generalized "risk" function, where $L_{xj}P_{j|x}$ is the contribution associated with classifying $\mathbf{x}$ to class j. From this perspective, (22) and (23) specify the optimal parameters as those providing the best risk tradeoff over the entire training set. The influence an individual classification decision has on the learning is proportional to its associated risk $L_{xj}P_{j|x}$. Moreover, for a given parameter, this influence also depends on the "tuning" of the parameter for the class output, i.e., the degree to which the parameter can affect the class output (and hence the ownership of the point). In (22), this "tuning" is measured by the sensitivity $\frac{\partial F_j(\mathbf{x})}{\partial \Lambda_k}$ relative to its average value over all classes. In (23), since γ linearly weights all class outputs, this sensitivity is simply the class output $F_j(\mathbf{x})$ relative to the average over all classes. Risk minimization normally involves making "hard" decisions. However, the entropy constraint, *which is explicit in the "risk" through the terms log* $P_{j|x}$, guarantees that $P_{j|x}$ remains "soft" at intermediate β to achieve a specified level of H while minimizing $< P_e >$.

We can easily relate these interpretations of our design procedure to a method that performs direct descent on $< P_e >$. Note that the necessary conditions for minimizing $< P_e >$ have the same form as (22) and (23) if we replace L_{xj} with $\delta(c,j)$. In this case, since there is no entropy term, minimization of the cost should be achieved by making the probabilities "hard." By contrast, in our approach a "hard" solution is only obtained for $\beta \to \infty$, i.e., when the Lagrangian is equivalent to $< P_e >$. At this limit, $\gamma \to \infty$, $\{P_{j|x} \to \{0,1\}\}$, $< P_e > \to P_e$, $F \to F_h$, and for the "winning" output class j, we have $L_{xj} = L_x$, $F_j(\mathbf{x}) = < F_l(\mathbf{x}) >_l$, and $\frac{\partial F_j(\mathbf{x})}{\partial \Lambda_k} = < \frac{\partial F_l(\mathbf{x})}{\partial \Lambda_k} >_l$. Thus, it is readily seen that for $\beta \to \infty$, the hard cost P_e is minimized, and the necessary optimality conditions are satisfied by sending $\gamma \to \infty$ so that the annealing method converges at the limit, maximizing F_h and achieving the structure (6).

D. Algorithm Description

Our annealing-based optimization method is a continuation method that tracks the parameters $\{\Lambda, \gamma\}$ that minimize the Lagrangian L for a sequence of increasing values of β (decreasing temperatures). The method starts at high temperature ($\beta = 0$) for which the Lagrangian cost is convex. Thus, the global minimum is found at high temperature, independent of initialization. The optimal parameters $\{\Lambda^*, \gamma^*\}$ found at a given β are then used as initialization for the optimization at the next (larger) β. At each β, L can be minimized by a gradient descent technique or any other function minimization technique. The partial derivatives in (22) and (23) can be used as the basis for a gradient descent procedure. The conditions (22) and (23) also specify a convergence condition for the optimization at given β. Alternatively, the convergence condition at given β may be based on diminishing values of the drop in L, i.e., the optimization stops at β if $\frac{\Delta L}{L} < \epsilon$ for specified ϵ. The annealing method terminates for a value of β at which the entropy H has dropped below a specified threshold level δ. At this point, the parameters Λ are used to specify a hard classification rule, as described in Section II-A. Thus, γ is not used by the final (hard) classifier.

E. Specialization to Different Structures

In this section, we specialize our general approach for three major classifier structures, deriving necessary optimality conditions for each structure. This will provide the basis for the corresponding algorithms used in our simulations.

1) Optimality Conditions for Nearest-Prototype Classifiers: The probabilistic associations have the form

$$P_{j|x} = \frac{\sum_k e^{-\gamma d(\mathbf{x},\mathbf{x}_{jk})}}{\sum_l \sum_m e^{-\gamma d(\mathbf{x},\mathbf{x}_{lm})}} \quad (24)$$

which reduce to the rule of (2) for $\gamma \to \infty$. Necessary conditions for minimizing L at any β are derived in a

[6] Here, we have used $< A_{xj} >_j$ to denote the average of a random quantity A_{xj} over the distribution $\{P_{j|x}\}$, i.e., $< A_{xj} >_j = \sum_j P_{j|x} A_{xj}$.

straightforward fashion and are found to be

$$\frac{\partial L}{\partial \mathbf{x}_{jk}} = 0 \Rightarrow \sum_{(\mathbf{x},c)\in\mathcal{T}} (L_{xj} - L_x) P_{jk|x} \frac{\partial d(\mathbf{x}, \mathbf{x}_{jk})}{\partial \mathbf{x}_{jk}} = 0, \forall j, k \tag{25}$$

and

$$\frac{\partial L}{\partial \gamma} = 0 \Rightarrow \sum_{(\mathbf{x},c)\in\mathcal{T}} \sum_j L_{xj} P_{j|x} (d_{xj} - d_x) = 0. \tag{26}$$

Here, d_{xj} is the average distance from $\mathbf{x}$ to a prototype from class j, i.e., $d_{xj} =< d(\mathbf{x}, \mathbf{x}_{jk}) >_k$, and d_x is the average distance to any prototype, i.e., $d_x =< d(\mathbf{x}, \mathbf{x}_{jk}) >_{jk}$. The condition for a prototype vector suggests moving it away from (or toward) the feature vectors that it "owns" probabilistically through $P_{jk|x}$ and for which L_{xj} is greater than (less than) the average L_x. The condition for γ suggests finding the value that achieves the best tradeoff between the (potentially) conflicting goals for individual data seeking to "harden" or "soften" ownership based on the associated risk.

2) Optimality Conditions for Radial Basis Functions: The probabilistic associations are those based on (13), using (4). Since the network outputs are linear in the weights $\{\lambda_{kj}\}$, γ is implicitly defined through the weight magnitudes. Prior to writing down necessary optimality conditions, it is helpful to first define several quantities: the difference $\Delta_{kj}(\mathbf{x}) = \lambda_{kj} - F_j(\mathbf{x})$ and this difference averaged over all classes, i.e., $< \Delta_{kj}(\mathbf{x}) >_j \equiv \Delta_k(\mathbf{x})$. Then, as a function of these quantities, the necessary optimality conditions are found to be

$$\frac{\partial L}{\partial \mu_k} = 0 \Rightarrow \sum_x \frac{\partial \phi_k(\mathbf{x})}{\partial \mu_k} \left(\sum_j P_{j|x} L_{xj} (\Delta_{kj}(\mathbf{x}) - \Delta_k(\mathbf{x})) \right) = 0, \forall k \tag{27}$$

$$\frac{\partial L}{\partial {\sigma_k}^2} = 0 \Rightarrow \sum_x \frac{\partial \phi_k(\mathbf{x})}{\partial {\sigma_k}^2} \left(\sum_j P_{j|x} L_{xj} (\Delta_{kj}(\mathbf{x}) - \Delta_k(\mathbf{x})) \right) = 0, \forall k \tag{28}$$

$$\frac{\partial L}{\partial \lambda_{kj}} = 0 \Rightarrow \sum_x \phi_k(\mathbf{x}) P_{j|x} (L_{xj} - L_x) = 0 \forall k, j. \tag{29}$$

As before, these conditions can be seen to specify a type of supervised learning rule that matches intuition. In (27) and (28), the influence an individual classification decision has on the learning is a function of the associated risk $L_{xj} P_{j|x}$, as well as the sensitivity of the class output to the given parameter. In this case, the sensitivity of class output $F_j(\mathbf{x})$ to changes in a parameter from receptive field k is $(\Delta_{kj}(\mathbf{x}) - \Delta_k(\mathbf{x})) \frac{\partial \phi_k(\mathbf{x})}{\partial \Lambda_k}$, where Λ_k is either the receptive field center or its width. Equation (29) is also directly interpretable; effectively, the weight from receptive field k to class j is increased (decreased) if L_{xj} is smaller (larger) than the average L_x.

3) Optimality Conditions for Multilayer Perceptrons: Using the probabilistic associations of (13) and the MLP recursion of (8), the optimality condition of (22) specializes to

$$\sum_x \sum_j P_{j|x} L_{xj} \tilde{\mathbf{u}}_{k-1} \left(\frac{\partial F_j(\mathbf{x})}{\partial \tilde{\mathbf{u}}_k} - < \frac{\partial F_l(\mathbf{x})}{\partial \tilde{\mathbf{u}}_k} >_l \right)^T \mathbf{f}_k{}'(\mathbf{v}_k) = 0 \; 0 \le k \le K \tag{30}$$

where $\mathbf{f}_k{}'(\mathbf{v})$, which is the derivative of layer k's outputs with respect to its activation level is a diagonal matrix with diagonal elements $\frac{\partial f_l(v_i)}{\partial v_i}$. The optimality condition for γ remains as in (23). The only elements of (30) that are not readily available are the terms $\frac{\partial F_j(\mathbf{x})}{\partial \tilde{\mathbf{u}}_k}$, which describe the network output sensitivity to hidden layer outputs. However, these can be conveniently computed using a backward recursion similar in spirit to standard backpropagation:

$$\frac{\partial F_j(\mathbf{x})}{\partial \tilde{\mathbf{u}}_{k-1}} = \mathbf{f}_k'(\mathbf{v}_k) \mathbf{W}_k \frac{\partial F_j(\mathbf{x})}{\partial \tilde{\mathbf{u}}_k} \; 1 \le k < K \; \forall j \tag{31}$$

with the initialization

$$\frac{\partial F_j(\mathbf{x})}{\partial \tilde{\mathbf{u}}_K} = \mathbf{e}_j \; \forall j \tag{32}$$

where $\mathbf{e}_j$ is the jth natural basis vector of $\mathcal{R}^{M_K+1}$ (the unit vector having value one at the jth component).

III. Experimental Comparisons

In this section, we demonstrate the performance of our design approach both on synthetic examples we have generated and on benchmark data obtained from the literature. Since our main focus is on comparing design methods, rather than classifier structures, we have performed separate experiments for each of the classifier structures. In each case, two types of comparisons may be indicated. The first relates to the performance achieved inside the training set, which demonstrates the ability of our method to optimize its design criterion and illustrates the problems of local optima for conventional design techniques as well. The second comparison involves the test set performance, which gives an indication of how well the methods generalize to new data. In addition to discussing the solution quality of the various designs, we will also consider other issues such as the design complexity. For all the DA algorithms that follow, steepest descent was used to minimize L at a sequence of exponentially increasing β given by $\beta(n+1) = \alpha\beta(n)$ for α between 1.05 and 1.1. We have found that especially for RBF and MLP design, much of the optimization occurs at or near a critical temperature in the solution process. Beyond this critical temperature, the annealing process can often be "quenched" to zero temperature by sending $\gamma \to \infty$ without incurring significant performance loss and with substantial reduction in design complexity. Quenching the process often makes the design complexity of our method comparable to (and in some cases smaller than) that of descent-based methods such as BP or gradient descent on $< P_e >$. In Fig. 4, we illustrate the basic annealing process, showing that with increasing inverse temperature β, H and $< P_e >$ are reduced, while F increases, eventually reaching the maximum value of F_h. The structure in this case was an RBF classifier trained on simulated data.

A. Prototype Examples

We have performed experimental comparisons of our nearest-prototype method with the learning vector quantizer (LVQ) [21]. As an example, consider the two-class data of Fig. 5. Each class consists of a Gaussian mixture with

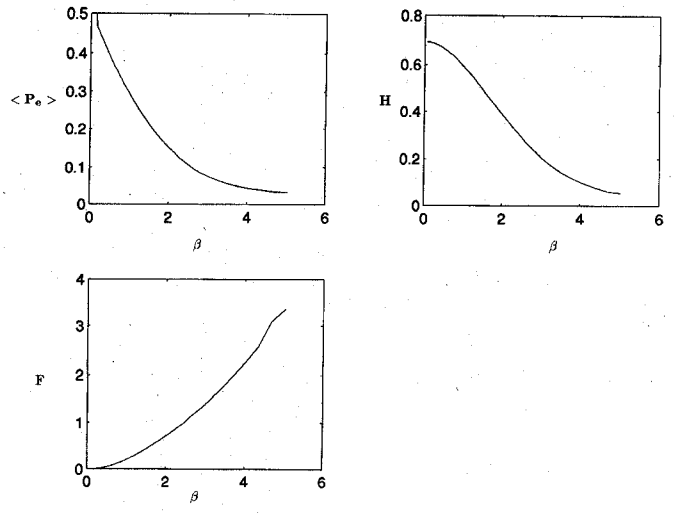

Fig. 4. Variation of entropy H, probability of error $< P_e >$, and the winner-take-all objective F with β during the training of an RBF classifier.

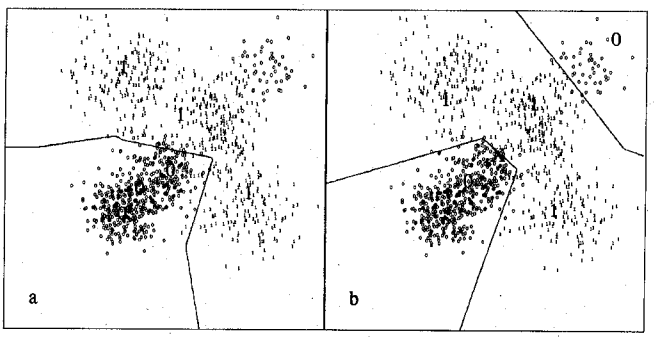

Fig. 5. Two-class example for prototype-based classifier design. Each class is a Gaussian mixture consisting of three components: (a) The best LVQ solution, using six prototypes, with $P_e = 7.7\%$. (b) The DA solution, using five prototypes, with $P_e = 2.7\%$. Note that since the solution at $\beta = 0$ placed all prototypes at the global centroid (X), the DA optimization has allowed a prototype for class 0 to "pass through a wall" of class 1 data in order to correctly classify the minority "0" mixture component.

three components. We designed prototype-based classifiers with three prototypes per class using both the LVQ and DA optimization methods. LVQ solutions were generated based on the public domain LVQ-pak software (version 2.1) running both an optimized LVQ (OLVQ) learning phase with 500 000 iterations, as well as a fine-tuning phase using LVQ1 with the learning parameter α set to 0.03. Ten LVQ solutions were generated based on different initializations produced by the LVQ-pak's *eveninit* routine. In all cases, the method was unable to discriminate the class 0 "minority" component in the upper right of Fig. 5(a) (which retains only 5% of the training set mass). Apparently, the initialization did not select a prototype from the class 0 minority component, and LVQ is unable to move class 0 prototypes through the "wall" of class 1 data that separates them from this component. The best LVQ solution, which is shown in Fig. 5(a), achieved $P_e = 7.7\%$. Increasing the number of prototypes, we found that LVQ was only able to discriminate the minority component when 21 prototypes per class were introduced, and in this case, the method achieved $P_e = 3.4\%$. While the extremity of this suboptimality suggests that the LVQ-pak initialization could be improved,[7] this example does demonstrate LVQ's susceptibility to finding poor solutions. In fact, we also performed gradient descent on $< P_e >$ and found that poor solutions were obtained in this case as well; except for omniscient initialization in the vicinity of the optimal solution, the best performance obtained for six prototypes was $P_e = 7.0\%$. It thus appears that strict descent methods will fail on this example unless given an excellent initialization. By contrast, the DA method using only five prototypes achieved the solution shown in Fig. 5(b), with $P_e = 2.7\%$. Note that the DA method is independent of the initialization, placing all prototypes together at the global data centroid (marked by X) at $\beta = 0$ to maximize entropy.[8] Then, as β is increased, the prototypes separate, reducing the entropy as well as $< P_e >$. This example demonstrates the ability of the method to avoid local optima since the DA optimization does succeed in moving a class 0 prototype from X directly *through* the class 1 data "wall" to correctly classify the minority class 0 component and achieve what appears to be the optimal piecewise linear result for the given number of prototypes. (Here, two of the class 0 prototypes are nondistinct; therefore, the solution effectively uses five prototypes.) The main point of this 2-D example is to visually illustrate the problem of local minima and the potential that DA has for avoiding them. For experiments involving high dimensional data sets (to be described shortly), visual illustration is not possible, but our results will likewise demonstrate that local minimum problems do exist and that the DA method can be applied to provide significant performance improvement.

We also tested our approach on the "synthetic" example from [35], as well as on some other complicated synthetically generated mixture examples. On the example from [35], our approach achieved $P_e = 8.9\%$ on the test set using eight prototypes and $P_e = 8.6\%$ using 12 prototypes, in comparison to LVQ's $P_e = 9.5\%$ based on 12 prototypes. For general reference, an MLP with six hidden units achieved $P_e = 9.4\%$. For complicated mixture examples, with possibly 20 or more overlapping mixture components and multiple classes, we have found our method to consistently achieve substantial performance gains over LVQ. As an example, consider the training data for a four-class problem involving 24 overlapping, nonisotropic mixture components in two dimensions as shown in Figs. 6 and 7. We designed NP-classifiers with 16 prototypes (four per class) using both LVQ and DA. Figs. 6(a) and 7(a) display the data and partitions formed by the two solutions. Figs. 6(b) and 7(b) display the prototype locations along with the partitions. The best LVQ solution based on 10 random initializations, which is shown in Fig. 6, achieved $P_e = 31\%$. Note that the method has failed to distinguish a component of class 0 in the upper left of Fig. 6(a), as well as a component of class 1 near the lower right of the figure.

[7] For example, if an initialization of prototypes based on isodata clustering followed by allocation of prototypes to the majority class of the cluster were used, much fewer than 42 prototypes (but greater than six) would suffice to find good solutions.

[8] Such an initialization is, in fact, "fatal" for a strict descent-based approach, as the associated learning rule will not permit a class 0 prototype to pass through the "wall" of class 1 data.

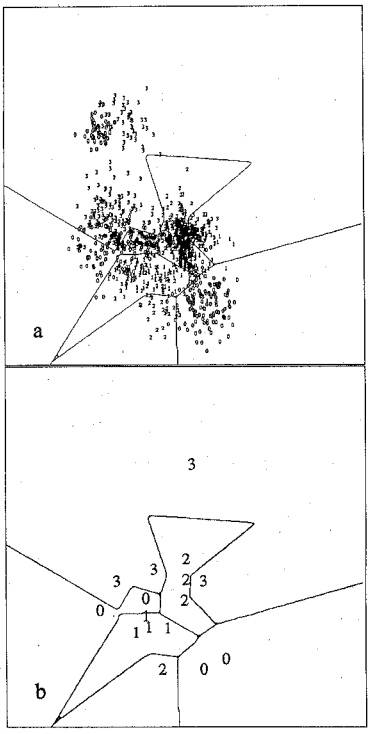

Fig. 6. (a) Four-class Gaussian mixture training set for a prototype-based classifier design and the partition produced by LVQ. (b) LVQ solution with the location of the 16 class prototypes shown. The error rate is $P_e = 31\%$.

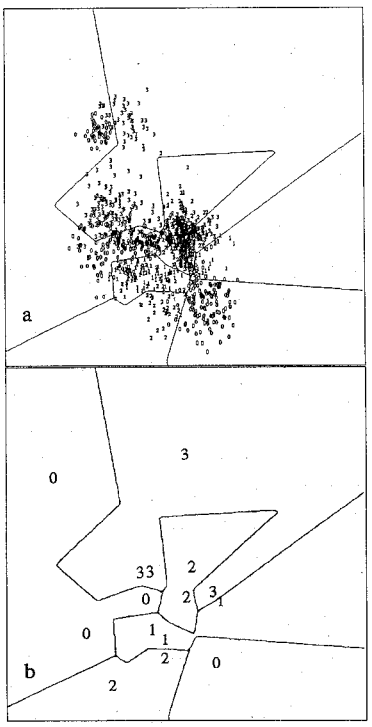

Fig. 7. (a) Four-class Gaussian mixture training set for a prototype-based classifier design and the partition produced by DA. (b) The DA partition with the 16 class prototypes shown. The error rate is $P_e = 23\%$.

By contrast, the DA solution shown in Fig. 7 succeeds in discriminating these components and achieves $P_e = 23\%$.

In addition to the above experiments, we tested our design approach on the Finnish phoneme data set that accompanies the standard LVQ package. The training set consists of 1962 vectors of 20 dimensions each. Each vector represents speech attributes extracted from a short segment of continuous Finnish speech. These vectors are labeled according to the phoneme uttered by the speaker during the corresponding segment. There are 20 classes of phonemes in the training set. In both LVQ and DA approaches, we set the number of prototypes associated with a particular class to be proportional to the relative population of that class in the training set. This is referred to as the *propinit* initialization in the standard LVQ package. We compared the performance of the DA and LVQ approaches over a range of values for the total number of prototypes. It was observed that the DA method consistently outperformed LVQ over the entire range. The experimental results are shown in Table I. This comparison is typical of what we have seen through extensive experimentation.

TABLE I
COMPARISON OF THE DA AND LVQ METHODS FOR DESIGNING PROTOTYPE-BASED CLASSIFIERS ON THE 20-DIMENSIONAL, 20 CLASS FINNISH PHONEME DATA SET THAT ACCOMPANIES THE STANDARD LVQ PACKAGE. M REPRESENTS THE TOTAL NUMBER OF PROTOTYPES

M (# of units)	20	30	40	50	80	100	200
P_e (LVQ)	13.25	12.44	11.47	10.96	10.09	8.17	6.78
P_e (DA)	11.67	9.99	8.36	5.55	4.83	4.23	3.26

B. RBF Examples

We have compared our RBF design approach with the method of Moody and Darken [29] (MD-RBF) with a method described by Tarassenko and Roberts [48] (TR-RBF) and with steepest descent on $< P_e >$ (G-RBF). MD-RBF combines unsupervised learning of receptive field parameters with supervised learning of $\{\lambda_{kj}\}$ to minimize the squared distance to target class outputs. The primary advantage of this approach is its modest design complexity. However, the receptive fields are not optimized in a supervised fashion, which can cause performance degradation. TR-RBF, which is one of the methods described in [48], optimizes all of the RBF parameters to approximate target class outputs in a squared error sense. This design is more complex than MD-RBF and achieves better performance for a given model size (the number of receptive fields the classifier uses). However, as discussed previously, the TR-RBF design objective is not equivalent to minimizing P_e, but, as in the case of BP, effectively aims to approximate the Bayes-optimal discriminant. While direct descent on $< P_e >$ may minimize the "right" objective, problems of local optima may be quite severe. In fact, we have found that the performance of all of these methods can be quite poor without a judicious initialization. For all of these methods, we have employed the unsupervised learning phase described in [29] (based on isodata clustering and variance estimation) as model initialization. Then, steepest descent was performed on the respective cost surface. We have found that the complexity of our design is typically 1–5 times that of TR-RBF or G-RBF (though, occasionally, our design is actually faster than G-RBF). Accordingly, we have chosen the best results based on five random initializations for these techniques and compared with the single DA design run.

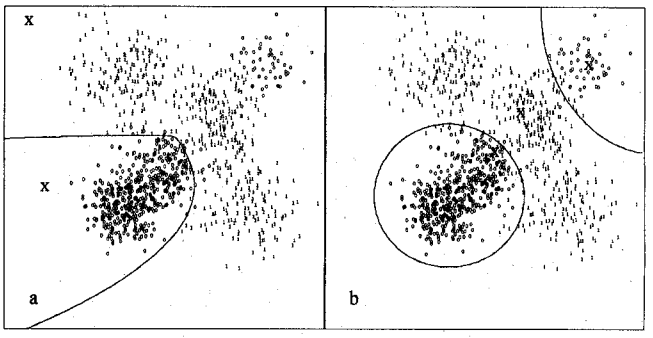

Fig. 8. (a) RBF classifier solution with three receptive fields, produced by the method from [38]. The error rate is $P_e = 7.0\%$. (b) The DA solution with three receptive fields, which yields $P_e = 2.7\%$. In each case, the receptive field "centers" are indicated with an X. Note that in (a), one of the "centers" lies outside the boxed area.

As a first example, we used the same training data of Fig. 5 (previously used to test the NP structure) to test RBF performance. In Fig. 8, X's are used to denote RBF centers. The best solution with $M = 3$ receptive fields achieved by TR-RBF is shown in Fig. 8(a), with $P_e = 7\%$. The DA solution for $M = 3$ is shown in Fig. 8(b), with $P_e = 2.7\%$. G-RBF with $M = 6$ obtained $P_e = 7.2\%$. While TR-RBF and G-RBF achieved good solutions by moderately increasing M (to $M = 4$ and 8 units, respectively), MD-RBF only obtained $P_e = 2.9\%$ by increasing M to 30.

To illustrate that increasing M may not help to improve performance on the *test* set, we compared our design with the results reported in [30] for 2-D and 8-D mixture examples. For the 2-D example, our method achieved $P_{e_{\text{train}}} = 6.0\%$ for a 400-point training set and $P_{e_{\text{test}}} = 6.1\%$ on a 20 000 point test set, using $M = 3$ units. (These results are near-optimal, based on the Bayes rate.) By contrast, the method in [30] used 86 receptive fields and achieved $P_{e_{\text{test}}} = 9.26\%$. For the 8-D example and $M = 5$, our method achieved $P_{e_{\text{train}}} = 8\%$ and $P_{e_{\text{test}}} = 9.4\%$ (again near-optimal), whereas the method in [30] achieved $P_{e_{\text{test}}} = 12.0\%$ using $M = 128$.

More comprehensive tests on higher-dimensional data have also been performed. Two examples reported here are the 21-D waveform data and the 40-D "noisy" waveform data used in [3] (which was obtained from the UC-Irvine machine learning database repository.) Rather than duplicate the experiments conducted in [3], we split the 5000 vectors into equal size training and test sets. Our results in Tables II and III demonstrate quite substantial performance gains over all the other methods and performance quite close to the estimated Bayes rate of 14% [3]. Note, in particular, that the other methods perform quite poorly for small M and need to increase M to achieve training set performance comparable to our approach. However, performance on the test set does not necessarily improve and may degrade for increasing M.

C. MLP Examples

We have compared the performance of our DA approach for designing MLP's with two other approaches: the standard BP algorithm of [42] and gradient descent on the $< P_e >$ cost surface (G-MLP). In our implementation of BP, we initialized

TABLE II
COMPARISON OF DA WITH KNOWN DESIGN TECHNIQUES FOR RBF CLASSIFICATION, ON THE 21-D WAVEFORM DATA FROM [3]. M IS THE NUMBER OF RECEPTIVE FIELDS. WE COMPARE OUR DA APPROACH WITH THE METHOD DESCRIBED IN [38] (TR-RBF), THE METHOD IN [22] (MD-RBF,) AND WITH GRADIENT DESCENT ON $< P_e >$ (G-RBF). THE TEST SET PERFORMANCES HAVE A MAXIMUM 95% CONFIDENCE INTERVAL OF HALF-LENGTH 2%

Method	DA	TR-RBF				MD-RBF		G-RBF

COMPARISON OF DA WITH KNOWN DESIGN TECHNIQUES FOR RBF CLASSIFICATION ON THE 40-D NOISY WAVEFORM DATA FROM [3]. THE TEST SET PERFORMANCES HAVE A MAXIMUM 95% CONFIDENCE INTERVAL OF HALF-LENGTH ABOUT 3.0%

Method	DA		TR-RBF				MD-RBF		G-RBF
M (# of units)	4	30	4	10	30	50	10	50	10
P_e (training set)	11.0	2.8	33.0	16.2	14.5	12.9	30.0	19.0	18.0
P_e (test set)	13.0	16.7	35.0	16.5	16.8	17.9	37.0	18.0	20.0

the weights to uniform random numbers between ± 0.01. Next, we used 50 000 epochs of a batch gradient descent algorithm to minimize the mean-squared error between the desired and actual outputs of the MLP. As discussed previously, BP descends on a cost surface mismatched to the minimum P_e objective. Further, its performance is heavily influenced by the choice of initial weights. In G-MLP, we attempted to improve the performance of BP by initializing the weights with the BP solution and then descending on $< P_e >$. However, in practice, we have found that the gains achieved by G-MLP over BP are only marginal as the optimization performance sensitively depends on the choice of initialization.

We have experimented on several 2–D examples and some examples with features of larger dimension. In all cases, the DA design approach produced significant performance improvements. First, we revisit the 2-D example used to test the other structures. We designed a sequence of neural networks for this example, each with a single layer of hidden neurons. Fig. 9(a) and (b) show partitionings of the input space generated by BP and DA, respectively. Fig. 9(a) is the BP solution using four hidden units, which failed to separate the small cluster of 0s in the top-right corner, achieving $P_e = 7.4\%$. Fig. 9(b) shows the partition generated by a DA solution with three hidden units, giving $P_e = 2.4\%$. Using the G-MLP design approach slightly improved on the performance of BP, reducing P_e to 7.2%. Although it is conceivable that BP or G-MLP would obtain the optimal solution with a fortuitous initialization, in our experiments, they required 10 hidden units to approach the performance of DA. Table IV shows the performance of the three methods for a variety of network sizes.

Another example we chose was the 19-D, seven-class image segmentation data from the UC-Irvine machine learning database. The training set contains 210 vectors, and the test set contains 2100 vectors, where each are 19-D. The features represent various attributes of a 3×3 block of pixels. The classes correspond to textures (brickface, sky, foliage, cement,

TABLE IV
MISCLASSIFICATION PERFORMANCE P_e FOR THE DA, BP, AND G-MLP DESIGN APPROACHES ON THE 2-D MIXTURE EXAMPLE. THE PERFORMANCE IS SHOWN FOR A VARYING HIDDEN LAYER SIZE (M). THE TEST SET PERFORMANCES HAVE A MAXIMUM 95% CONFIDENCE INTERVAL OF HALF-LENGTH ABOUT 0.3%

	DA		BP				G-MLP			
M	3	4	3	4	8	10	3	4	8	10
P_e (training set)	2.4	2.4	7.8	7.4	7.4	3.0	7.4	7.4	7.4	3.0
P_e (test set)	3.8	2.4	7.4	7.2	6.8	4.2	7.2	7.0	7.2	4.4

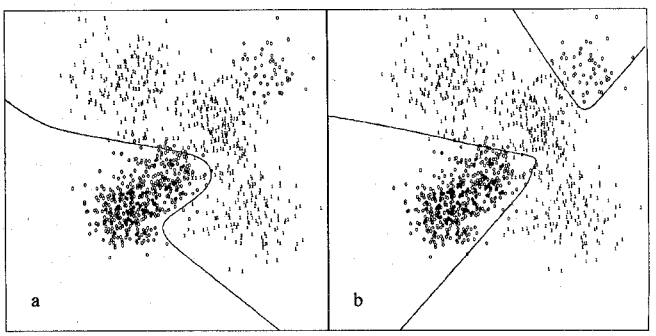

Fig. 9. (a) MLP solution with four hidden units found by BP, with $P_e = 7.4\%$. (b) The DA solution with three hidden units and $P_e = 2.4\%$.

TABLE V
MISCLASSIFICATION PERFORMANCE P_e FOR THE DA, BP, AND G-MLP DESIGN APPROACHES ON THE 19-D SEVEN-CLASS SEGMENTATION DATA EXAMPLE. THE TEST SET PERFORMANCES HAVE A MAXIMUM 95% CONFIDENCE INTERVAL OF HALF-LENGTH 2.1%

	DA			BP				G-MLP			
M	4	6	8	4	6	8	10	4	6	8	10
P_e (training set)	19.1	8.1	6.2	45.7	31.9	20.0	6.1	45.7	31.4	19.6	6.0
P_e (test set)	20.1	11.2	10.5	48.1	31.7	25.3	13.3	47.2	34.4	23.2	13.0

window, path, grass). We designed a sequence of single hidden layer neural networks for this data set. Table V summarizes the results we obtained for various hidden layer sizes (M). Networks designed by DA significantly outperformed the other approaches over the entire range of network sizes.

An important concern is the issue of design complexity. In our experiments, we have found the DA learning complexity to be roughly 4–8 times higher than that of BP and roughly the same as that of G-MLP. This suggests that the potential for performance improvement would, in typical applications, greatly outweigh the somewhat higher design complexity of the DA approach.

IV. CONCLUSIONS

In this paper, we introduced a new design method for statistical classifiers aimed at minimizing the cost of misclassification. The method is based on ideas from statistical physics and information theory and extends the deterministic annealing method both to incorporate structural constraints as well as to minimize the probability of error as the cost. The design methodology is general and applicable to a variety of classifier structures. We have specialized the general approach to obtain specific design algorithms for three distinct, commonly used classifier structures—NP, MLP, and RBF classifiers. For each structure, our design approach yielded better classifiers than those obtained by other known methods. For some problems in pattern classification, where the NP, MLP, and RBF classifiers are used, the design methods presented here are immediately applicable. For other application areas, in particular, speech recognition and character recognition, more powerful classifier structures such as hidden Markov models are typically needed to exploit the dependence (either in time or space) between class labels of "neighboring" features. More work is needed to apply the design philosophy presented here to such structures. Optimization of these structures may be pursued in future work. Another potential area of investigation is the extension of the ideas we have developed here to address related optimization problems in source coding and statistics that involve "embedded" classifiers. These include the design of structured vector quantizers and generalized vector quantizers [11], as well as the problem of piecewise regression. Some promising work has already been done in the source coding context [33].

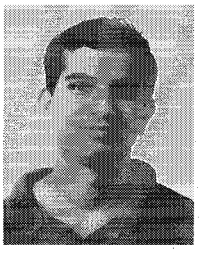
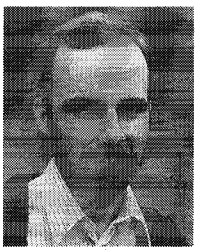
David Miller (S-87–M'95) received the B.S.E. degree from Princeton University, Princeton, NJ, in 1987, the M.S.E. degree from the University of Pennsylvania, Philadelphia, in 1990, and the Ph.D. degree from the University of California at Santa Barbara in 1995, all in electrical engineering.

From January 1988 through January 1990, he was employed by General Atronics Corporation, Wyndmoor, PA. Since August 1995, he has been an assistant professor of electrical engineering at the Pennsylvania State University, University Park. His research interests include source and channel coding, image compression, statistical pattern recognition, and neural networks.

Dr. Miller received the National Science Foundation Career Award in 1996 for the continuation of his research on learning algorithms for neural networks.



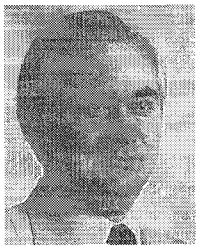
Ajit V. Rao (S'93) was born in Mangalore, India, in 1971. He received the B.Tech. degree in electronics and communication engineering in 1992 from the Indian Institute of Technology, Madras, India, and the M.S. degree in electrical and computer engineering in 1993 from the University of California, Santa Barbara, where he is currently pursuing the Ph.D. degree. In the summer of 1995, he worked as an intern in the Speech Coding group at Texas Instruments Inc., Dallas, TX. His current interests are speech and image coding and statistical pattern recognition.



Kenneth Rose (S'85–M'91) received the B.Sc. degree (summa cum laude) and the M.Sc degree (magna cum laude) in electrical engineering from Tel-Aviv University, Israel, in 1983 and 1987, respectively, and the Ph.D. degree in electrical engineering from the California Institute of Technology (Caltech), Pasadena, in 1990.

From July 1983 to July 1988, he was employed by Tadiran Ltd., Israel, where he carried out research in the areas of image coding, transmission through noisy channels, and general image processing. From September 1988 to December 1990, he was a graduate student at Caltech. In January 1991, he joined the Department of Electrical and Computer Engineering at the University of California, Santa Barbara, where he is currently an associate professor. His research interests are in information theory, source and channel coding, pattern recognition, image coding and processing, and nonconvex optimization in general.

Dr. Rose was co-recipient of the William R. Bennett Prize Paper Award of the IEEE Communications Society in 1990.



Allen Gersho (S'58–M'64–SM'78–F'81) received the B.S. degree from the Massachusetts Institute of Technology, Cambridge, in 1960 and the Ph.D. degree from Cornell University, Ithaca, NY, in 1963.

He is Professor of Electrical and Computer Engineering at the University of California, Santa Barbara (UCSB). He was at Bell Laboratories from 1963 to 1980. His current research activities are in signal compression methodologies and algorithm development for speech, audio, image, and video coding. He holds patents on speech coding, quantization, adaptive equalization, digital filtering, and modulation and coding for voiceband data modems. He is co-author with R.M. Gray of the book *Vector Quantization and Signal Compression* (Boston: Kluwer, 1992) and co-editor of two books on speech coding.

Dr. Gersho served as a member of the Board of Governors of the IEEE Communications Society from 1982to 1985 and is a member of various IEEE technical, award, and conference management committees. He has served as Editor of *IEEE Communications Magazine* and Associate Editor of the IEEE TRANSACTIONS ON COMMUNICATIONS. He received NASA "Tech Brief" awards for technical innovation in 1987, 1988, and 1992. In 1980, he was co-recipient of the Guillemin–Cauer Prize Paper Award from the Circuits and Systems Society. He received the Donald McClennan Meritorious Service Award from the IEEE Communications Society in 1983, and in 1984, he was awarded an IEEE Centennial Medal. In 1992, he was co-recipient of the 1992 Video Technology Transactions Best Paper Award from the IEEE Circuits and Systems Society.
